Key Words: Electroencephalography, EEG, Amplitude-integrated EEG, Intensive care, Neonatal seizures, Hypoxic ischemic encephalopathy.

(*J Clin Neurophysiol* 2011;28: 611–617)

This article offers the preferred methods and indications for long-term, conventional electroencephalography (EEG) monitoring for selected, high-risk neonates of postmenstrual age less than 48 weeks. The authors recognize that there may be significant practical barriers to the implementation of these recommendations for many caregivers and institutions, particularly with regard to the availability of equipment, and technical and interpretive personnel. A wide range of clinical circumstances dictates the implementation of EEG monitoring, frequency of EEG review, and the subsequent treatment of seizures or EEG background abnormalities detected by neonatal EEG. Consequently, this article should be considered as an expression of idealized goals and not as a mandated standard of care.

INDICATIONS FOR CONVENTIONAL ELECTROENCEPHALOGRAPHY MONITORING IN NEONATES

Use of Long-Term Electroencephalography Monitoring to Evaluate Electrographic Seizures

Differential Diagnosis of Abnormal Paroxysmal Events

Electroencephalography monitoring can be used to clarify whether sudden, stereotyped, unexplained clinical events are seizures. Because epileptic seizures are common in acutely ill newborns (Clancy et al., 2005; Eriksson and Zetterstrom, 1979; Gluckman et al., 2005; Lanska et al., 1995; Ronen et al., 1999; Saliba et al., 1999), are difficult or impossible to accurately identify and quantify by visual inspection alone (Clancy and Legido, 1988; Murray et al., 2008), may contribute to or amplify adverse outcomes (McBride

et al., 2000; Wyatt et al., 2007), and are potentially treatable by the administration of antiseizure medications (Painter et al., 1999; Rennie and Boylan, 2007; Silverstein and Ferriero, 2008), the largest role of EEG monitoring is the surveillance for and prompt treatment of electrographic seizures. Clinical signs such as abrupt, repetitive, or abnormal appearing movements, atypical behaviors or unprovoked episodes of autonomic dysfunction may be the outward clinical expression of neonatal seizures (Table 1). It is acknowledged that the yield of EEG monitoring to confirm the epileptic basis of isolated, paroxysmal *autonomic* signs (e.g., isolated paroxysmal increases in the heart rate or blood pressure) is low (Cherian et al., 2006; Clancy et al., 2005); however, when episodes of autonomic dysfunction are the result of seizures, they can only be accurately identified by EEG monitoring.

Detection of Electrographic Seizures in Selected High-Risk Populations

In many high-risk populations, neonatal seizures are common, but most are *subclinical* (i.e., they have no outwardly visible clinical signs and may only be identified by EEG monitoring). Such electrographic seizures are referred to by various names, such as *nonconvulsive*, *silent*, *occult*, or *electrographic-only* seizures (Clancy and Legido, 1988; Murray et al., 2008; Scher et al., 1993; 2003). The proportion of subclinical seizures is lowest among those who are naive to antiseizure medication treatment (Bye and Flanagan, 1995; Clancy and Legido, 1988; Pisani et al., 2008). However, once antiseizure medications are administered, up to 58% of treated neonates exhibit electroclinical uncoupling, in which the clinical signs of their seizures vanish despite the persistence of subclinical electrographic seizures (Scher et al., 2003).

1. *Clinical settings in which to suspect neonatal seizures:* Infants who are at a high risk for acute brain injury, those with demonstrated acute brain injury, and those with clinically suspected seizures or neonatal epilepsy syndromes are at high risk for electrographic seizures and should be considered as candidates for long-term EEG monitoring (Table 2). Furthermore, neonates in high-risk clinical settings who are iatrogenically paralyzed by the administration of neuromuscular blocking agents, precluding accurate neurologic examination, may require EEG monitoring to accurately detect seizures.
2. *Monitoring for seizure recurrence during or after weaning antiseizure medications:* Although there are no published data (as of February, 2011) to support or refute this practice, some centers use EEG monitoring during and after the withdrawal of antiseizure medications to screen for recurrent seizures. The committee members agreed that indications for EEG monitoring during or after medication withdrawal depend on the underlying cause of the neonatal

TABLE 1. Examples of Sudden, Stereotyped Clinical Events That May Raise the Suspicion for Neonatal Seizures

Focal clonic or tonic movements
Intermittent forced, conjugate, horizontal gaze deviation
Myoclonus
Generalized tonic posturing
“Brainstem release phenomena” such as oral–motor stereotypes, reciprocal swimming movements of the upper extremities or bicycling movements of the legs
Autonomic paroxysms such as unexplained apnea, pallor, flushing, tearing, and cyclic periods of tachycardia or elevated blood pressures

seizures. For example, seizures in neonates with acute acquired brain injury (e.g., arterial ischemic stroke or hypoxic-ischemic encephalopathy) are unlikely to recur soon after the resolution of the acute phase. Conversely, neonates at a high risk for seizure recurrence (e.g., cerebral dysgenesis or malformations, tuberous sclerosis or neonatal epilepsy syndromes) may have a relapse of seizures if medications are withdrawn. Therefore, the decision to monitor (or not to monitor) as antiseizure medications are adjusted must be tailored to the individual’s clinical circumstance.

3. *Monitoring burst suppression:* EEG monitoring should be used to quantify the duration of the interburst periods in those

TABLE 2. Examples of High-Risk Clinical Scenarios Which May Lead to Consideration of Long-Term Neonatal EEG Monitoring

Examples of Clinical Scenarios Conferring High Risk of Neonatal Seizures

Clinical syndrome of acute neonatal encephalopathy
Neonatal depression from suspected perinatal asphyxia (chronic or acute)
After cardiopulmonary resuscitation
Cardiac or pulmonary risks for acute brain injury and clinical encephalopathy
Significant respiratory conditions such as severe persistent pulmonary hypertension
Need for ECMO
Congenital heart defects requiring early surgery using cardiopulmonary bypass
CNS infection
Laboratory confirmed meningoencephalitis
Suspected CNS infection, such as clinical evidence in setting of maternal chorioamnionitis, funisitis, group B streptococcus or HSV colonization
CNS trauma
Intracranial subarachnoid, subdural, or intraventricular bleeding
Clinical encephalopathy and suspicion for CNS injury, for example, maternal trauma, traumatic delivery, prolonged second stage of labor, or suspected nonaccidental trauma
Inborn errors of metabolism (suspected or confirmed)
Perinatal stroke (suspected or confirmed)
Sinovenous thrombosis (suspected or confirmed)
Premature infants with additional risk factors
Acute high-grade intraventricular hemorrhages
Very low birth weight with clinical concern for encephalopathy
Genetic/syndromic disease involving CNS
Cerebral dysgenesis on neuroimaging
Dysmorphic features or multiple anomalies with microcephaly

ECMO, extracorporeal membrane oxygenators; CNS, central nervous system; EEG, electroencephalography; HSV, Herpes simplex virus.

who undergo deliberate pharmacologic suppression of EEG, such as with pentobarbital or midazolam for treatment-resistant status epilepticus, and to detect break-through seizures. In other contexts, such as severe metabolic encephalopathies because of neonatal citrullinemia with marked hyperammonemia, the duration of the interburst intervals progressively declines as the hyperammonemia is corrected by medical intervention (Clancy and Chung, 1991).

Use of Long-Term Electroencephalography Monitoring to Judge the Severity of an Encephalopathy

There are broader applications for neurophysiologic monitoring in the neonatal intensive care setting beyond seizure detection alone (Scher, 2005). Most types of neonatal encephalopathy are represented by a spectrum of severities. This is reflected in the familiar Sarnat encephalopathy scale in which the clinical grades of encephalopathy are ranked from stages 1 to 3, depending on the depth of abnormalities of mental status, neuromuscular tone and activity, and muscle stretch or bulbar reflexes (Sarnat and Sarnat, 1976). Likewise, EEG background abnormalities parallel the degree and course of encephalopathy. As such, EEG backgrounds may demonstrate subtle or mild abnormalities in those with modest degrees of acute encephalopathy, moderate background abnormalities in those with intermediate severity injuries, or severe abnormalities in those with profound acute brain injuries (Holmes and Lombroso, 1993). Thus, serial assessment of the EEG background serves the role of following the dynamic, evolving character of an acute encephalopathy and providing a sensitive and specific prognostic tool for predicting survival or long-term disability.

Electroencephalography Monitoring for the Assessment of Background Abnormalities During Acute Neonatal Encephalopathy

Continuous or serial EEG studies offer important information regarding the degree of neonatal encephalopathy. In acute encephalopathies that occur at or near the time of birth, severe background abnormalities (e.g., burst suppression, low voltage invariant, isoelectric, asynchrony, asymmetry and others) define the functional extent of the global brain injury and are reliable prognostic indicators (reviewed in Holmes and Lombroso, 1993). Major EEG background disturbances resolve or evolve over days to weeks into alternate expressions of persistent brain disorders, as the infant is tracked from the acute through the convalescent phases of an acute encephalopathy. Therefore, obtaining serial EEG studies can assist the treating clinicians in providing prognostic information for the encephalopathic newborn. The most appropriate timing of these recordings depends on the clinical circumstances.

It is prognostically favorable to see the return of sleep state cycling after acute hypoxic-ischemic encephalopathy. As recognizable state transitions return after the acute phase of an encephalopathy, a routine 1 hour recording may be incapable of documenting both active and quiet sleep segments because many lack the normal 1 hour neonatal ultradian sleep rhythm (Scher, 2008). Consequently, abnormalities of the neonatal EEG/sleep cycle may be more reliably detected during prolonged (3 to 4 hours) or serial recordings. Finally, the use of an expanded array of recording electrodes such as those used in routine neonatal EEG may be required, including relevant polygraphic data (e.g., electrocardiogram, respirations, oxygenation, extraocular movements and electromyogram). Such comprehensive multichannel recordings most accurately localize regional or

hemispheric cerebral activities, stage neonatal sleep, describe specific behaviors (possibly with concurrent video monitoring) and detect artifact.

Electroencephalography Monitoring for the Assessment of Background Abnormalities After Neonatal Encephalopathies of Prenatal Origin

Many causes of neonatal encephalopathy discovered at birth have a significant *prenatal* origin or contribution (Hankins and Speer, 2003). Consequently, EEG examinations immediately after birth may miss the most abnormal findings that are ordinarily used to formulate an estimate of prognosis. Indeed, some nonspecific normalization of the background can occur even in the wake of a severe injury. In those who have already transformed to a subacute or chronic phase of encephalopathy by the time of birth, EEGs may already have evolved to express only milder features of neurophysiologic dysfunction. In the future, computer analyses of EEG/sleep recording may augment our ability to detect and classify these more subtle expressions of dysfunction, using frequency and time-dependent analytic strategies (Scher, 2004). Currently, researchers are evaluating the utility of multichannel EEG/sleep recordings in conjunction with computer-generated evoked potential findings (i.e., visual, auditory, somatosensory) to offer both region-specific diagnostic information throughout the neuroaxis involving specific neuronal networks as well as relevant prognostic information (Guerit et al., 2009).

Dysmature Electroencephalography Examinations

The concept of dysmaturity has evolved in the specific context of serial EEG examinations in very premature infants. In general, the appearance of a premature infant's EEG background is determined solely by their postmenstrual age, obtained by adding the estimated gestational age to the legal age. Skilled EEG readers can estimate a patient's postmenstrual age within ± 2 weeks by assessing the development of sleep states, number and distribution of delta brushes, type of discontinuity in quiet sleep and the appearance of specific transients such as encoches frontales (a.k.a frontal sharp transients). Some very premature babies, especially those with severe lung disease, have a chronic encephalopathy during which postnatal brain development may be delayed, resulting in anatomical and functional immaturity. Correspondingly, they may show EEG *dysmaturity* detected by serial EEG examinations. For example, if a 36-week postmenstrual age infant displays the overall EEG characteristics typical of a 32-week postmenstrual age infant, the gap between the actual postmenstrual age and the patient's age suggested by their EEG characteristics is physiologic evidence of dysmaturity. In general, studies of prognosis based on EEG findings use the results of routine-length EEGs rather than long-term EEG monitoring. In the case of *chronic* injuries, which may evolve over extended time periods, more pervasive electrographic/polygraphic disturbances are more easily diagnosed using multiple, serial EEG/sleep recordings, of sufficient duration to capture both wakefulness and sleep, if such state changes exist, with important prognostic implications (Monod et al., 1972; Tharp et al., 1981).

PROCEDURES FOR NEONATAL ELECTROENCEPHALOGRAPHY MONITORING

1. The Committee endorses the American Clinical Neurophysiology Society's Guidelines on the Minimum

FIG. 1. The International 10-20 System for electrode placement, modified for neonates. The circled electrode positions are included in the typical neonatal montage. Note that some laboratories use an alternate location for the position of the frontal polar electrodes. The neonatal electrode designation "FP₃" is located halfway between the conventional electrode locations of FP₁ and F₃. Similarly, the neonatal electrode position "FP₄" is halfway between the conventional electrode positions of FP₂ and F₄. Note also that not all the laboratories use the Pz electrode. Alternate terminology designates "FP" electrodes as "AF," T_{3/4} as T_{7/8}.

Technical Standards for pediatric EEG (Epstein, 2006). Electrodes should be placed according to the International 10-20 system, modified for neonates (Fig. 1). A full array of electrodes may be placed, according to the International 10-20 system, but this is not mandatory. In addition to scalp electrodes, extracerebral channels including electrocardiogram and respiratory channels, should be used. Eye leads (for electrooculogram) and surface electromyography leads are often useful but are not universally required.

2. Conventional EEG is typically recorded with surface electrodes. Silver and gold electrodes are available. The former provides a lower impedance while the latter are compatible with magnetic resonance imaging. Although some centers use needle electrodes for neonatal EEG monitoring, this is not a mandated practice. Computerized tomography and magnetic resonance imaging-compatible EEG electrodes are becoming available but require administrative approval and acceptance by individual radiology departments.
3. Several neonatal EEG montages are in common use. Typically a single neonatal montage is adequate for long-term monitoring. Examples are listed in Table 3.
4. *Concurrent conventional EEG and reduced electrode EEG monitoring (amplitude-integrated EEG [aEEG]):* When single-channel aEEG recordings are obtained in isolation, the recommended electrode locations are P3 and P4 because they overlie the apices of the cerebrovascular watershed zones (Hellström-Westas et al., 2008) and have been shown to detect more seizures than frontal electrodes (Wusthoff et al., 2009). When reduced channel aEEG is

*Additional channels may be added for eye leads, chin electromyography, and nasal thermistor respiration measurements.

obtained simultaneously to complement ongoing conventional EEG monitoring. P3 and P4 may be added to the conventional recording montage. Alternatively, the nearby C3 and C4 electrodes may be substituted by electrode splitters. When two-channel aEEG is used to complement conventional EEG, the electrode pairs C3/P3 and C4/P4 are most commonly recommended. Single or dual channel aEEG can provide useful information regarding the neonatal EEG background for the selected central or parietal regions, although the data provided by conventional EEG are more nuanced and allow the detailed evaluation of particular brain regions. The aEEG is less sensitive for the detection of neonatal seizures (Rennie et al., 2004; Shah et al., 2008; Shellhaas et al., 2007) compared with long-term monitoring by conventional EEG. Using multi-channel aEEG (with eight channels) may improve seizure detection (Bourez-Swartz et al., 2009; Stewart et al., 2010). This is further discussed in the subsequent digital trending and analysis section.

5. *The use of synchronized video monitoring:* Synchronized video is strongly recommended for the characterization of events and is often helpful in assessing for artifacts that may mimic electrographic seizures. Such artifacts include: chest physical therapy, patting, sucking on a pacifier or endotracheal tube, high frequency or conventional ventilation artifacts, extracorporeal membrane oxygenator pump artifacts, electrocardiogram, pulsatile fontanelle, or other environmental or electrical interference.
6. *Importance of a bedside observer:* Even when video is being recorded, a bedside observer who can document the occurrence of key clinical events electronically or in a bedside log and push the EEG event button is recommended. If time-locked video recording is not available, then a bedside observer is required. Key events could include suspected seizures or clinical events, chest physical therapy, neuroactive drug administration, the initiation of hypothermia or rewarming, and similar pertinent occurrences that could influence the appearance of the EEG. While electrographic seizures can be identified without a bedside

observer, nonseizure events are difficult to recognize without observer documentation. Bedside observers can enter a text description for the event on the digital EEG file at the time of the event. Alternatively, the bedside log should contain a description of the events, along with the date and time.

7. *Duration of EEG recording:* The indication for EEG evaluation determines the most appropriate duration of EEG monitoring and should be modified as appropriate by the results of the EEG examination.
 - i. The EEG background assessment requires a minimum of 1 hour of recording time to allow analysis of sleep-wake cycling, if present.
 - ii. The Committee recommends that neonates at high risk for seizures (Table 2) be monitored with conventional EEG for 24 hours to screen for seizures. Seizures suspected by aEEG were documented in more than half of term neonates with hypoxic-ischemic encephalopathy who fulfilled the criteria for selective head cooling within 6 hours of birth (Gluckman et al., 2005) and studies of neonates undergoing EEG monitoring during therapeutic hypothermia for hypoxic-ischemic encephalopathy have also demonstrated a high incidence of seizures (Nash et al., 2011). After newborn heart surgery, seizures occurred at a mean of 21 hours (range 10 to 36 hours) postoperatively (Clancy et al., 2005) and always within 22 hours in another more heterogeneous group of high-risk neonates (Laroia et al., 1998). Published data indicate that seizures may occur even in the presence of a normal or mildly abnormal EEG background (Korff and Nordli, 2005; Shellhaas and Clancy, 2007). Therefore, for high-risk infants (as described in Tables 1 and 2), a 1-hour EEG is considered inadequate to screen for seizures. In consultation with a neurologist, some lower risk infants may be identified and at the discretion of the clinical team EEG monitoring may be appropriately discontinued sooner than 24 hours.
 - iii. If seizures are detected, it is recommended that EEG monitoring continue until the patient has been found to be seizure-free for at least 24-hours, unless in consultation with a neurologist a decision is made to discontinue monitoring earlier. While there are no published data on the recurrence of seizures after 24 hours of seizure-freedom (as of March 2011), this is a customary practice among child neurologists.
 - iv. Although contemporary published data on this topic are not available, the Committee recommends that EEG monitoring for the differential diagnosis of suspicious clinical events should continue until multiple typical events are captured. If an adequate sample of typical events are captured and lack an associated electrographic seizure, then monitoring for that purpose may be discontinued. Likewise, if the clinical episodes resolve spontaneously, EEG monitoring may be discontinued.

TRAINING OF CARETAKERS

Appropriate neonatal EEG monitoring requires a team of trained caretakers, including nurses, EEG technologists, neonatologists, pediatricians, neurologists, and clinical neurophysiologists with training in neonatal EEG acquisition and interpretation.

ELECTROENCEPHALOGRAPHY INTERPRETATION AND REPORTING

1. *EEG interpretation by the clinical neurophysiologist:* We recognize that a wide range of clinical circumstances influence EEG review practices and treatment strategies as dictated by institutional resources. Remote access to EEG tracings facilitates timely interpretation. The first hour of EEG recording should be interpreted as soon as possible by the clinical neurophysiologist and the results conveyed to the treating clinicians. The frequency of subsequent review depends on the clinical scenario. At a minimum, the EEG tracing should be reviewed by the clinical neurophysiologist at least twice per 24-hour epoch, and more often as clinically indicated. The EEG should be re-reviewed according to clinical circumstances (e.g., if bedside clinicians report the occurrence of a suspicious event of interest or after a therapeutic intervention has been implemented or adjusted to evaluate for treatment response).
2. *Electroencephalography review by the EEG technologist and nursing staff:* Ideally, the EEG technologist should remain at the bedside for the first hour of recording to ensure a high quality recording and to make note of relevant clinical signs. Thereafter, the EEG technologist should reevaluate the quality of the EEG recording frequently and adjust recording leads as necessary. The bedside nurse should also evaluate the quality of the recording periodically and should contact the technologist if the tracing is suboptimal.
3. *Reporting EEG results:* Results of the EEG monitoring should be communicated formally to the treating clinicians at least daily. Interim verbal reports should be provided to the clinical team as needed. Written reports should be part of the medical record and should be completed daily, including assessment of the EEG background, seizures, and push-button events. This recommendation applies to both conventional and reduced-montage EEG recordings (e.g., aEEG).

DATA RETENTION and STORAGE

1. *Data storage:* Ideally, EEG data should be recorded and stored in nonproprietary or publicly available formats to ensure that the tracings can be viewed using various manufacturers' software and/or equipment (for details, see American Clinical Neurophysiology Society Guidelines, available at www.acns.org). In addition, it should be possible to provide a disk on request that includes the EEG recording and appropriate review software.
2. *Data retention:* The EEG monitoring centers should review their institutional and/or state guidelines for their mandated duration of data storage. Where institutional and/or state guidelines are lacking, discussion with the center's legal counsel is warranted. Typically, it is medically indicated to archive EEG recordings for the immediate future, and regulations may require the data to be retained for 7 years or until the patient reaches 18 years of age, whichever is longer. Data storage guidelines apply to all formats of EEG recordings, regardless of the number or type of electrodes applied. Therefore, data derived from reduced-montage EEG devices (e.g., aEEG) should be stored according to the same regulations that apply to conventional EEG. Trend data need not be stored separately, because they can be recreated from the original EEG recording.

DIGITAL TRENDING and ANALYSES

Trend analyses represent a variety of mathematical signal transformations of one or more channels of EEG, which are then displayed on a compressed time scale. Trends provide a condensed overview of prolonged EEG recordings, allowing the interpreter to view a compressed representation of an extended epoch of EEG recording in a single graph. They are useful in summarizing long-term trends, the presence of sleep-wake cycling and targeting specific regions of interest for detailed review (e.g., to evaluate for suspected seizures) during prolonged recordings. However, time compression may result in obscuration of brief clinical or EEG events. Conventional EEG is usually interpreted on a time scale of 15 to 30 mm of recording per second. In contrast, the typical display of aEEG, is 6 cm/hour, thus compressing the time scale of conventional EEG by a factor of up to 900:1. The mathematical transformation used depends on the type of information desired. Some trending approaches are commercially available and others exist only in the research realm. It is beyond the scope of this article to exhaustively list or examine all available digital trending algorithms, particularly because this is an evolving field and few data directly pertinent to neonates are available.

In the newborn, digital trending has been used mainly to analyze the EEG background, and seizure detection has been a secondary goal. The most commonly used digital trends are discussed below. Except for aEEG, few data exist to support or refute their use for neonatal monitoring. However, because many of these modalities are used concurrently with conventional EEG monitoring (e.g., digital trending is displayed at the bedside while full-array EEG is recorded) and aEEG is a widely used monitoring tool in neonatal intensive care units, the committee reviewed the modalities below.

1. *Amplitude-integrated EEG* is the most commonly used digital trend for newborns and its use has been integrated as a customary practice for assessment of EEG background in many intensive care nurseries (Boylan et al., 2010; Filan et al., 2007; Ponnusamy et al., 2010; Toet and Lemmers 2009). This trending modality modifies the raw EEG by filtering frequencies less than 2 Hz and more than 15 Hz, rectifying and smoothing the signal, and uses a semilogarithmic amplitude compression (with a linear display for 0 to 10 μ V and logarithmic display for 10 to 100 μ V) before displaying it in a time-compressed manner with 6 cm/hour of recording, as previously mentioned. Full technical details of aEEG are provided in excellent reviews (Hellström–Westas et al., 2006; 2008). Compared with management based on clinical seizure detection alone, the use of aEEG has been shown to reduce the total seizure duration in neonates (van Rooij et al., 2010).

The original aEEG monitors used a single channel of "raw" EEG (filtered as described above) derived from EEG leads placed in the parietal (P3 and P4) positions. The parietal region was originally selected because it is over the cerebrovascular watershed, an area at high risk for acquired injury. However, the adjacent C3 and C4 channels probably provide comparable data for single-channel aEEG. Most contemporary machines now allow the display of dual channel recordings (e.g., C3 \rightarrow P3 and C4 \rightarrow P4), along with the raw EEG from which the aEEG signals are derived, providing the opportunity to detect interhemispheric asymmetries. Because seizure detection is impeded by artifact and inadequate ability to detect ictal patterns from the frontal electrodes, this committee discourages frontal electrode placement for aEEG recordings (Wusthoff et al., 2009).

Conventional video-EEG monitoring is the gold standard for neonatal seizure detection and quantification and should be used

whenever available for seizure detection and differential diagnosis of abnormal appearing, paroxysmal clinical events. It is the ideal tool to measure the exact number and duration of seizures, their site(s) of onset and spatial patterns of migration. However, if there are obstacles in obtaining conventional EEG monitoring, then aEEG can be a useful, initial complementary tool. Because of data showing poorer sensitivity and specificity for seizure detection (Rennie et al., 2004; Shah et al., 2008; Shellhaas et al., 2007) single and dual channel aEEG alone are not recommended for this purpose if conventional EEG is available. If seizures are suspected on aEEG, this committee recommends that conventional EEG monitoring, if available, should begin as soon as possible to confirm and refine the electrodiagnosis. The aEEG using multiple channels or averaged groups of electrodes (hemispheric or regional) can be considered as an adjunct to conventional EEG monitoring (Bourez-Swart et al., 2009; Stewart et al., 2010). Some neonatal intensive care units record conventional EEG, but display aEEG on the bedside monitor, to facilitate real-time bedside interpretation while allowing subsequent confirmation by neurophysiologists interpreting the conventional EEG recording.

The sensitivity of aEEG for neonatal seizure detection is limited. Using single-channel aEEG, without raw single-channel EEG for confirmation, individual seizure detection is less than 50% (Rennie et al., 2004; Shellhaas et al., 2007) and depends on the interpreter's level of expertise. Although the addition of a second aEEG channel along with the ability to review raw EEG improves the sensitivity (up to 76%, with 78% specificity, in one study using aEEG experts [Shah et al., 2008]), seizure detection remains difficult with this tool (Shah et al., 2008). The committee acknowledges, however, that it is unknown whether such suboptimal seizure detection impacts clinical outcomes. Compared with management based on clinical seizure detection alone, the use of aEEG has been shown to reduce the total seizure duration in neonates (van Rooij et al., 2010).

The aEEG for background assessment (rather than seizure recognition) has been shown to provide early prognostic information in infants with hypoxic-ischemic encephalopathy (al Naqeeb et al., 1999; Hellström-Westas et al., 1995; Shalak et al., 2003; Toet et al., 1999). Amplitude-integrated EEG may be useful for risk stratification for clinical trials (Azzopardi et al., 2009; Gluckman et al., 2005), although some argue against its use for the determination of study eligibility for therapeutic hypothermia protocols (Sarkar et al., 2008).

2. *Density spectral array* displays EEG spectral power as a gray-scale or color plot, with time on the x-axis, frequency on the y-axis, and the power in gray scale or color scale. Power can be calculated for a specific set of electrodes, or can be averaged over a group of electrodes (e.g., a cerebral quadrant or hemisphere). Analysis of the raw EEG is important to exclude artifact, which causes increased activity in all frequencies, and thus translates to increased power, mimicking seizures. This trend is preferred by many neurophysiologists and neurointensivists and is used as an adjunct to standard EEG recording in critically ill adults and children. Further study is required before the committee can endorse widespread clinical use of the density spectral array for neonatal seizure detection.

3. *Envelope trend* displays the median amplitude of successive EEG epochs. Using median amplitudes reduces the appearance of transient high amplitude waveforms that are commonly caused by artifacts. This modality can be used to identify some seizures, although movement artifact during an electroclinical seizure may contaminate the envelope trend. Furthermore, brief and slowly evolving seizures remain very difficult to detect with envelope trend

(Abend et al., 2008). Further study is required before the committee can endorse widespread clinical use of envelope trend for neonatal seizure detection.

4. *Seizure detection and background grading algorithms* are a topic of intense ongoing research (e.g., Mitra et al., 2009; Temko et al., 2009). Data suggest that accurate seizure detection requires neonatal-specific algorithms, which many investigators are working to develop. However, current commercially available algorithms have poor sensitivity and specificity.

LEGAL IMPLICATIONS OF THE PRESENT CONSENSUS STATEMENT

This consensus statement is offered as a preferred set of goals for neonatal EEG monitoring and is not intended as a mandated standard of care. The Committee underscores the lack of evidence that neonatal EEG monitoring, seizure identification, or treatment of seizures, impacts long-term clinical outcomes. Therefore, while there is general consensus that longitudinal characterization of the EEG background, along with seizure identification and management are important, the Committee emphasizes that any EEG recording is better than none at all and that delayed detection of seizures is better than no recognition of these events. The committee further recognizes that transporting neonates to centers for the sole purpose of obtaining conventional EEG monitoring may be detrimental to some patients and is not currently considered a standard of care.
